Introduction

Background & Relevant Work

There are 18.8 million Americans living in food deserts today — areas with limited access to affordable and nutritious food. The USDA has defined food deserts to be census tracts that have a poverty rate of 20% or greater (or median family income that is less than 80% of statewide family income) and where at least 33% of the population live more than 1 mile from the supermarket in an urban area/ 10 miles in a rural area. Food deserts are created by distance from healthy food sources, usually influenced by structural decisions that have historically limited healthy food access for minority communities. Understanding this issue requires examining how redlining policies institutionalized neighborhood disinvestment, disproportionately exposing low-income and minority communities to less healthy food environments. These disparities carry serious consequences: food deserts are linked to worse health outcomes, including shorter life expectancy and a higher risk for adverse cardiovascular events. Given these health risks and the disproportionate racial impact of food deserts, it is critical to evaluate what factors contribute to their persistence and how current policy can work toward reversing years of racial residential segregation.

This issue is particularly relevant to us as Duke students, as 9 of the top 10 states with the greatest share of residents living in food deserts are in the South. In particular, North Carolina is one of the top 10 agricultural states in the US, but its food insecurity rate is 13.9% — 2.2

percentage points higher than the national average. This proximity makes understanding the structural drivers of food deserts a matter of community concern. Thus, I seek to answer the following question: what features can best explain whether a census tract is a food desert (classified as a low-income, low-access area) in North Carolina?

Studies have found that neighborhood racial composition and poverty rates are associated with food store availability. Interestingly, this study notes that these associations vary by rural and urban regions, which is why interventions should be developed locally rather than universally. A cross-sectional survey of randomly selected households in public housing communities in Baltimore, MD found that indivduals with a personal vehicle were more likely to report ease in reaching health food stores as compared to others.

Data & Key Variables

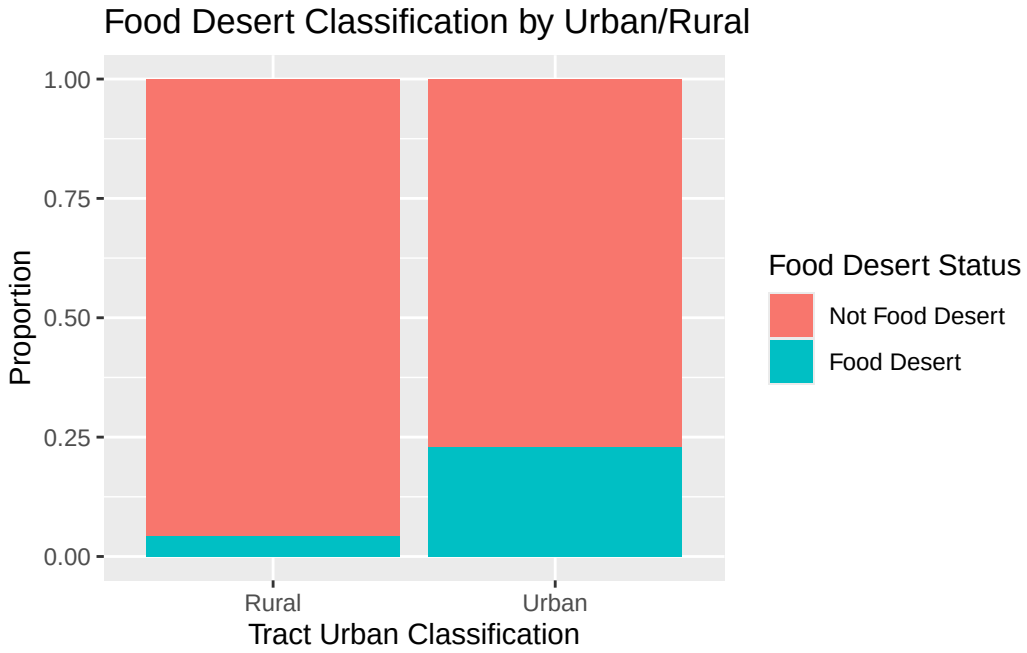

I will use the USDA's 2019 Food Research Atlas dataset to investigate my question and choose key predictors to understand patterns of food access in North Carolina. The 2019 Food Access Research Atlas provides an overview of food access indicators in the US by measuring variables like supermarket accessibility, race, poverty rate, and median income. This dataset is a combination of data collected by the 2010 Decennial Census, the 2014-18 American Community Survey (ACS), and two 2019 lists of supermarkets, one being from Trade Dimensions TDLinx. Observations are at the census tract level and therefore may not be independent, as nearby census tracts are likely to exhibit similar patterns in food desert status and food desert predictors. To address this limitation, I will take a random sample of 20% from the North Carolina subset of the dataset.

There is also substantial missing data in the `LALOWI1_10` variable, which represents the amount of people living in a low access, low income area. Thus, I will use the `LILATracts_1AND10` response variable, which is an indicator variable of what `LALOWI1_10` measures — whether a tract is classified as low income and low access (food desert). The `MedianFamilyIncome` variable also has 17 missing observations. However, since this is not a significant portion of the data for the NC sample (17 missing out of 448 observations), I will delete these observations rather than impute counts, so as not to assume patterns for certain areas. As a result, I also acknowledge that this data may not be entirely representative of the entire state, especially if those null values were concentrated in a specific area.

To understand factors that contribute to a census tract's categorization as low-income and low-access (or being a food desert), I will focus on the `LILATracts_1And10` response variable as a proxy measure for food desert (as it fits the USDA's definition of a food desert) and the following predictor variables: `Urban` , `TractSNAP` , `TractHUNV` , `PovertyRate` , `MedianFamilyIncome` . `Urban` is an indicator variable that classifies a census tract as urban or not using the official definition by the US Census (urban area has more than 2,500 people). This predictor will contribute to understanding whether food deserts vary by urbanicity, which is helpful in understanding where policymakers should direct resources to address such issues. Next,

`TractSNAP` will detail the number of housing units within a census tract receiving SNAP benefits. The rationale behind including this predictor is that communities with more individuals receiving SNAP benefits are also likely to be underresourced, characteristic of food deserts. `TractHUNV` provides information on number of housing units with access to a vehicle, which could illuminate the low access to grocery stores aspect of the food desert definition. Finally, `MedianFamilyIncome` and `Urban` will both be used to determine the general economic state of families in a census tract.

Exploratory Data Analysis

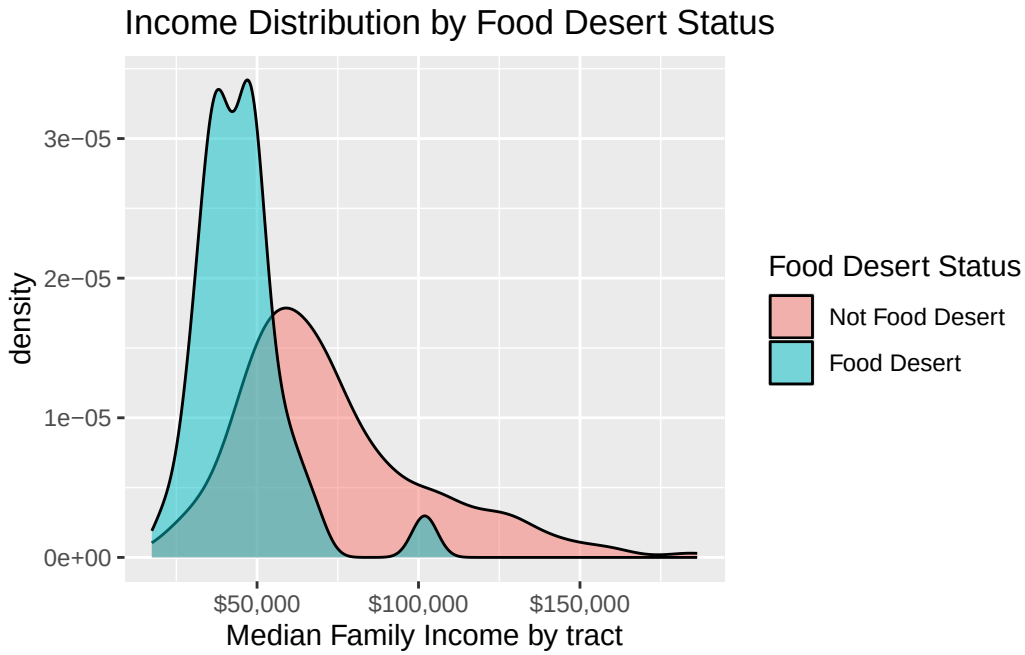

The map illustrates how the majorty of North Carolina does not contain areas classified as food deserts. More specifically, it shows that food deserts are concentrated in small areas around the state, and viewed in conjunction with the stacked bar chart, we understand that census tracts classified as food deserts are primarily also categorized as urban areas. To be specific, 84% of census tracts in NC are not food deserts. Due to this class imbalance, it is likely that the model fit on this data will not be accurate at predicting tracts that are food deserts, so I will gear my model selection toward explaining factors that contribute to food deserts.

Each of the quantitative predictors (`PovertyRate`, `TractSNAP`, `TractHUNV`, `MedianFamilyIncome`) have a unimodal and slightly right-skewed distribution. `Urban` shows a similar pattern of positive skew as the majority of census tracts in North Carolina (around 62%) are classified as urban. To ensure that the relationships between the quantitative predictors and the response is linear, I plotted each against the predicted probability of being a food desert and confirmed

linear relationships. This helped me determine not to log-transform the predictors when fitting my logistic regression model.

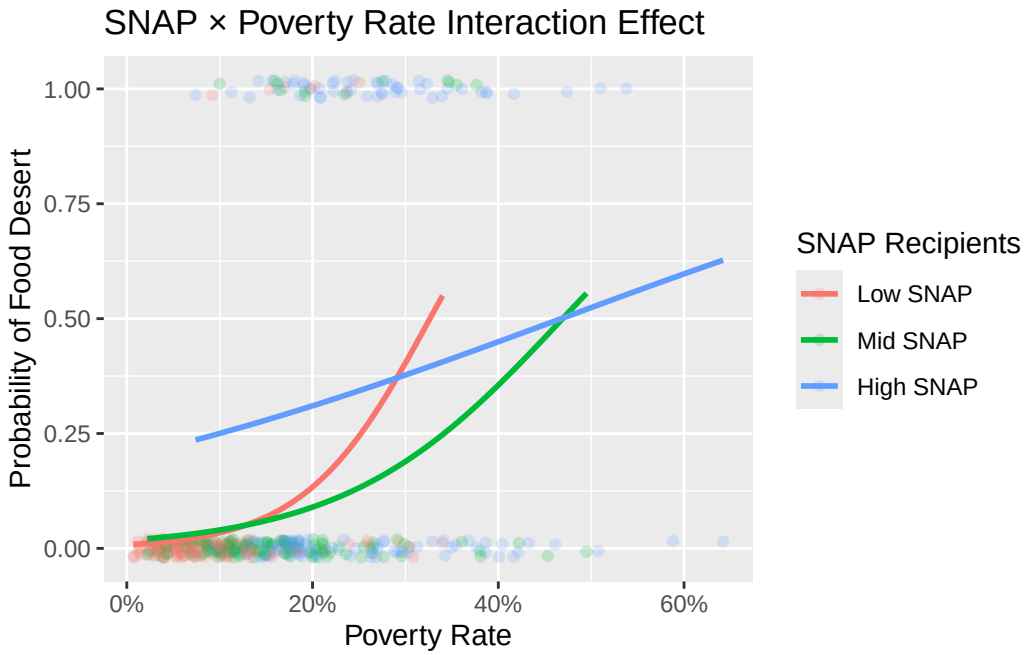

Due to this skew, the median is a good indicator of the center of the distribution for each of the variables. Thus, we see that the median poverty rate in NC is about 14.30%, which is higher than the United States' official 10.6% poverty rate. There are also some insignificant outlying census tracts with poverty rates above 50%. On average, 188 housing units in a census tract receive SNAP benefits. The IQR for this distribution is 255 housing units, which seems relatively large, but considering the fact that a census tract can range anywhere from 1,200 to 8,000 people, this spread is understandable. Traditionally, 80 housing units in a census tract do not have access to a vehicle. This is surprisingly low but realistic since a car is a necessity in most parts of NC due to the state's lack of public transportation. The relatively smaller spread (IQR=11) is in line with our understanding of NC's public infrastructure and the necessity of a vehicle, regardless of income status. Finally, `MedianFamilyIncome` has a distribution very similar to `PovertyRate` , which is not unexpected since both are roughly measuring the economic state of a census tract. There is a center around $61,500 median family income per census tract, much lower than the US's $83,000 median household income. The spread of the distribution (IQR) is about $20,000, with outliers above median family incomes of $150,000.

The double-density plot reveals that median family income is more variable among food desert tracts than non-food desert tracts. For instance, tracts that are not food deserts have a similar center to tracts that are food deserts, but the median incomes are more spread out from $45,000 to $125,000, while median incomes for food desert tracts are mostly concentrated

around $45,000 to $50,000. This distinction suggests a strong association between median family income and food desert status.

Interestingly, when observing the relationship of the quantitative predictors and the response variable, there are more outliers and a higher spread for non-food desert tracts. This may be due to less uniformity in socioeconomic characteristics among non–food desert tracts.

My key variables assess the geographic makeup of a tract (`Urban`) as well as poverty or economic status of individuals within the tract (`MedianFamilyIncome` , `PovertyRate` , `TractHUNV` , and `TractSNAP`). Since SNAP benefits are determined by relative income level and poverty rate, I visualize the interaction between the number of households receiving snap benefits in a tract and the tract poverty rate. According to the plot, there appears to be an interaction effect, as the slopes of the lines — representing different levels of snap receipt — differ. Most interesting is that tracts with a high number of SNAP recipients do not see as drastic an increase in the probability of being a food desert as poverty rate increases, as compared to tracts with a low number of SNAP recipients. This pattern could be explained by the fact that if a tract has a high number of households receiving SNAP benefits, then it is already more likely to be classified as a food desert, hence the flatter slope as poverty rate increases. For tracts with a low number of households receiving SNAP benefits, poverty rate then serves as an important metric of food desert status, which could explain the sharp increase in probability of being a food desert with each 1 percentage point increase in poverty rate.

In working with health and social science data, I am also cognizant of confounding being a limitation. This dataset does not provide a comprehensive account of all the factors that impact whether a census tract is a food desert since other variables can influence this measure/

the measure of other predictors. For instance, the `TractHUNV` predictor measures the number of housing units without a vehicle in a certain tract. Though the absence of a vehicle can make healthy food inaccessible, and therefore contribute to the categorization of an area as a food desert, the variable does not give a complete picture of accessibility — especially since access to public transportation is not considered. I will remain mindful of these limitations and incorporate them into my interpretation of the model to ensure that my conclusions are statistically sound and representative of the data.

Methodology

We will fit a logistic regression model to predict what factors contribute to food deserts across counties in North Carolina. This model is best suited for my dataset because I wish to predict whether a specific census tract is or is not classified as a food desert. Since this is represented as a probability of being a food desert (binary choice), logistic regression will help make such a prediction. To select an explanatory model, I calculated AIC and BIC for the following models.

1.Geographical Model: $\log\left(\frac{\hat{\pi}_i}{1-\hat{\pi}_i}\right) = \hat{\beta}_0 + \hat{\beta}_1 \cdot \text{Urban}_i$

2. Poverty Model: $\log\left(\frac{\hat{\pi}_i}{1-\hat{\pi}_i}\right) = \hat{\beta}_0 + \hat{\beta}_1 \cdot \text{MedianIncome}_i + \hat{\beta}_2 \cdot \text{SNAP}_i + \hat{\beta}_3 \cdot \text{HUNV}_i + \hat{\beta}_4 \cdot \text{PovertyRate}_i$

3. Combined Model: $\log\left(\frac{\hat{\pi}_i}{1-\hat{\pi}_i}\right) = \hat{\beta}_0 + \hat{\beta}_1 \cdot \text{Urban}_i + \hat{\beta}_2 \cdot \text{MedianIncome}_i + \hat{\beta}_3 \cdot \text{SNAP}_i + \hat{\beta}_4 \cdot \text{HUNV}_i + \hat{\beta}_5 \cdot \text{PovertyR}$

4. Interaction Model: $\log\left(\frac{\hat{\pi}_i}{1-\hat{\pi}_i}\right) = \hat{\beta}_0 + \hat{\beta}_1 \cdot \text{Urban}_i + \hat{\beta}_2 \cdot \text{MedianIncome}_i + \hat{\beta}_3 \cdot \text{SNAP}_i + \hat{\beta}_4 \cdot \text{HUNV}_i + \hat{\beta}_5 \cdot \text{PovertyR}$

$$\hat{\pi}_i$$

where $\hat{\pi}_i$ represents the probability a census tract is a food desert

Testing each of these models allowed me to understand which interactions and predictors were most helpful in explaining the existence of a food desert census tract in NC. AIC/BIC revealed that the models with the lowest scores were the combined model (AIC: 255.682; BIC: 280.0789) and the interaction model (AIC: 255.481; BIC: 283.944). Since the difference in AIC was negligible — and BIC prioritizes prediction and parsimonious models — I used variance inflation factors and a drop in deviance test to further confirm which model to use.

Computing the variance inflation factors for both models revealed no multicollinearity. Finally, to understand if the interaction effect is truly a necessary addition for explaining variation in predicted probabilities of a food desert tract, I conducted a drop-in-deviance test. The test showed a p-value of 0.138, which is greater than the significance threshold of 0.05 and therefore not a significant impact. Hence, I selected the final model to be the combined model with as `Urban` , `MedianFamilyIncome` , `TractSNAP`, `TractHUNV`, and `PovertyRate` as predictors.

Despite the distributions of the predictors demonstrating some right skew, I ultimately did not log transform them in the model. To make this decision, I binned and plotted each quantitative predictor against the log odds of being a food desert and found a straight, linear relationship for each. This pattern confirmed the fulfillment of the model conditions for logistic regression.

Finally, I computed Cook's Distance for the chosen model and confirmed that the data does not present any significant outliers that could impact the model's fit.

Results

In this section, you will present the final model and include a brief discussion of the model assumptions, diagnostics, and any relevant model fit statistics.

This section also includes initial interpretations of key model coefficients and discussion of inferential conclusions drawn from the model. The goal is not to interpret every single variable in the model but rather to show that you are proficient in using the model output to address the research question, using the interpretations to support your conclusions. Focus on the variables that help you answer the research question and that provide relevant context for the reader.

do cross validation later to see how well model generalizes to unseen data

term	estimate	std.error	statistic	p.value
(Intercept)	2.64776	1.42883	0.68148	0.49557
MedianFamilyIncome	0.99992	0.00002	-4.41224	0.00001
UrbanUrban	14.66438	0.46789	5.73944	0.00000
TractSNAP	1.00379	0.00123	3.08236	0.00205
TractHUNV	0.99599	0.00212	-1.89358	0.05828
PovertyRate	0.96283	0.02436	-1.55498	0.11995

Model assumptions and diagnostics

Logistic regression requires that observations are independent, that the log-odds of the outcome have a linear relationship with continuous predictors, and that there is no severe multicollinearity among predictors. The independence assumption is partially addressed by our random

20% sample of North Carolina census tracts, which reduces (though does not eliminate) the spatial dependence among neighboring tracts. Linearity in the log-odds was assessed through the EDA and transformation of `TractHUNV` to address its strong right skew. Regarding multicollinearity, the VIF scores for the additive model were all below about 3, indicating no problematic collinearity among the predictors. The inflated VIFs in the interaction model (MedianFamilyIncome: 20.97, Urban1: 25.31, interaction term: 45.16) are expected to be results of including an interaction term rather than evidence of true multicollinearity. Finally, Cook's distance confirmed no influential outliers that would affect model fit.

Model Fit

The interaction model was selected over the additive model based on AIC and BIC, despite a non-significant drop-in-deviance test ($p = 0.485$).The lower AIC suggests the interaction model should predict slightly better, and since the income $\times$ urbanicity interaction makes theoretical sense, supported by the data exploration, it is reasonable to keep it.

Interpretation

While the per-dollar odds ratio appears negligible for median family income, the negative z-statistic confirms that higher income is associated with lower odds of food desert classification. Thus, though the coefficient interpretation is negligible (for each one-unit increase in median family income, the odds that the tract is a food desert are expected to change by approximately 0% on average, holding all else constant), there is at least slight indication by the z statistic that economic resources can be a structural predictor of food access.

TractSNAP is also statistically significant, indicating that for each additional household receiving SNAP benefits in a tract, the odds that the tract is a food desert are expected to increase by 0.3% on average, holding all else constant. This positive association suggests that higher SNAP participation is linked to greater food access limitations, showing that financial assistance alone may not fully address barriers to accessing healthy food.

`PovertyRate` is potentially significant with a p-value of 0.065 in the model and worth investigating. Interestingly, the test statistic is negative, suggesting that an increase in poverty rate is associated with lower odds of a food desert. This pattern contradicts much of the literature on food access and food deserts, so a potential explanation for this direction of change could be collinearity in the model. Regardless, this example demonstrates the importance of interpreting results in context as well as verifying with the literature some examined patterns.

Conclusions

Altogether, the model suggests that economic measures, such as median family income and SNAP benefit receipt, are the most consistent predictors of food desert classification among

North Carolina census tracts. The role of the other predictors is more complex, since the higher p-values do not allow us to comment on the significance of those predictors and patterns they illuminate about food access. Cross-validation will be used to further evaluate the model's predictive performance on unseen data, particularly given the class imbalance of 84% of census tracts being categorized as not a food desert.

Discussion
